

Contact-normal drift: insufficient time coverage

Numerical near-rigid assumption only. No material calibration or manipulation-success claim.

At production dt, contact first appears in the final saved state at 4 ms for ring and little.

Middle contact never appears before the force stop. Each active pair has only one sampled contact state.

Computed displacement/angle from the first observation is therefore zero by construction.

This is NOT evidence of stable normals, stable topology or zero migration under sustained preload.

No steady window, 3 s comparison or valid multi-contact stability inference is available.
